Abstract

Runtime Verification (RV) is a lightweight method for monitoring the formal specification of a system during its execution. It has recently been shown that a given state predicate can be monitored consistently by a set of crash-prone asynchronous distributed monitors, only if sufficiently many different verdicts can be emitted by each monitor. We revisit this impossibility result in the context of LTL semantics for RV. We show that employing the four-valued logic RV-LTL will result in inconsistent distributed monitoring for some formulas. Our first main contribution is a family of logics, called LTL\textsuperscript{2k+4}, that refines RV-LTL incorporating \(2k+4\) truth values, for each \(k \geq 0\). The truth values of LTL\textsuperscript{2k+4} can be effectively used by each monitor to reach a consistent global set of verdicts for each given formula, provided \(k\) is sufficiently large.

Our second main contribution is an algorithm for monitor construction enabling fault-tolerant distributed monitoring based on the aggregation of the individual verdicts by each monitor.

1 Introduction

Runtime Verification (RV) is a technique where a monitor process determines whether or not the current execution of a system under inspection complies with its formal specification. The state-of-the-art RV methods for distributed systems exhibit the following shortcomings. They (1) employ a central monitor, (2) employ several monitors but lack a systematic way to monitor formally specified properties of a system (e.g., [11–13]), or (3) assume a fault-free setting, where each individual monitor is resilient to failures [6,8,9,16–18,21]. Relaxing the latter assumption, that is, handling monitors subject to failures, poses significant challenges as individual monitors would become unable to agree on the same perspective of the execution, due to the impossibility of consensus [10]. Thus, it is unavoidable that individual monitors emit different local verdicts about the current execution, so that a consistent global verdict with respect to a correctness property can be constructed from these verdicts.

The necessity of using more than just the two truth values of Boolean logic is a known fact in the context of RV with a single monitor. For instance, RV-LTL [4] has four truth values \(\mathbb{B}_4 = \{\top, \bot, \top_p, \bot_p\}\). These values identify cases where a finite execution (1) permanently satisfies, (2) permanently violates, (3) presumably satisfies, or (4) presumably violates an LTL formula. For example, consider a request/acknowledge property, where a
request $r_1$ is eventually responded by acknowledgment $a_1$, and $a_1$ should not occur before $r_1$; i.e., LTL formula $\varphi = G(\neg a_1 \land \neg r_1) \lor [(\neg a_1 U r_1) \land Fa_1]$. In $Rv$-LTL, a finite execution containing $r_1$ and ending in $a_1$ (i.e., the request has been acknowledged) yields the truth value ‘permanently satisfied’, whereas an execution containing only $r_1$ (i.e., the request has not yet been acknowledged) yields ‘presumably violated’.

Although $Rv$-LTL can monitor $\varphi$ (see Fig. 1 for its monitor automaton) in a centralized setting, we show $\mathbb{B}_4$ is not sufficient to consistently monitor a conjunction of two such formulas in a framework of several asynchronous unreliable monitors. Namely, the set of verdicts emitted by the monitors may not be sufficient to distinguish executions that satisfy the formula from those that violate it. Intuitively, this is because each monitor has only a partial view of the system under scrutiny, and after a finite number of rounds of communication among monitors, still too many different perspectives about the global system state remain. In fact, it was proved in [13] using algebraic topology techniques [14] that fault-tolerant distributed monitoring requires that the individual verdicts are taken from a set whose size depends on the formula being monitored.

**Our results.** In this paper, we propose a framework for distributed fault-tolerant RV. To this end, we make a novel connection between RV and consensus in a failure-prone distributed environment by proposing a multi-valued temporal logic. This new logic is a refinement of $Rv$-LTL. More specifically, we propose a family of $(2k + 4)$-valued logics, denoted $\mathit{LTL}_{2k+4}$, for $k \geq 0$. In particular, $\mathit{LTL}_{2k+4}$ coincides with $Rv$-LTL when $k = 0$. The syntax of $\mathit{LTL}_{2k+4}$ is identical to that of LTL. Its semantics is based on $F\mathit{LTL}$ [15] and $\mathit{LTL}_3$ [5], two LTL-based finite trace semantics for RV. For each $k \geq 0$, the $k$th instance of the family has $2k + 4$ truth values, that intuitively represent a degree of certainty that the formula is satisfied. We characterize the formulas that when verified at run time with $\mathit{LTL}_{2k+4}$, no additional information is gained if they are verified with $\mathit{LTL}_{2k'+4}$, for a larger value $k'$. We present a monitor construction algorithm that generates a finite-state Moore machine for any given $\mathit{LTL}$ formula and $k \geq 0$.

For example, for formula $\varphi = \varphi_1 \land \ldots \land \varphi_t$, where each $\varphi_i$ is an independent request/acknowledgment formula, $\mathit{LTL}_{2k+4}$ can be used to consistently monitor $\varphi$, whenever $k \geq t$. In particular, when $t = 2$, the set of truth values is $\mathbb{B}_8 = \{ T_0, \bot_0, T_1, \bot_1, T_2, \bot_2, T, \bot \}$. Moreover, formula $\varphi$ evaluates to $T_0$ (presumably true with the lowest degree of certainty) in a finite execution that does not contain neither $r_1$ nor $a_1$, then to $T_1$ in an extension where $r_1$ appears (presumably true with a higher degree of certainty), to $T_1$ in an extension that includes both $r_1$ and $a_1$, to $\bot_2$ if $r_2$ appears, and finally to $T$ (permanently true) in an execution that contains $r_1$, $a_1$, $r_2$, and $a_2$.

Our second contribution is an algorithm for fault-tolerant distributed RV, where the monitors are asynchronous wait-free processes that communicate with each other via a read/write shared-memory, and any of them can fail by crashing. (For simplicity we use this abstract model, which is well-understood [3, 14], and is known to be equivalent, with respect to task computability, to a message-passing model where less than half the processes can crash.) Each monitor gets a partial view of the system’s global state, communicates with the other monitors a fixed number of rounds, and then emits a verdict from $\mathbb{B}_{2k+4}$. We show how, given any LTL formula and a large enough $k$, the truth values of $\mathit{LTL}_{2k+4}$ can be effectively used such that a set of verdicts collectively provided by the monitors can be mapped to the verdict computed by a centralized monitor that has full view of the system under inspection. It follows from the general lower bound result in [13] that our algorithm is optimal, meaning that for any $k \geq 0$, there exists an LTL formula that cannot be monitored consistently in...
LTL\(2k+4\), if \(k\) is not sufficiently large. Finally, we prove that the value of \(k\) is solely a function of the structure of the LTL formula.

**Related Work.** While there has been significant progress in sequential monitoring in the past decade, there has been less work devoted to distributed monitoring. Lattice-theoretic centralized and decentralized online predicate detection in distributed systems has been studied in [8,16]. This line of work does not address monitoring properties with temporal requirements. This shortcoming is partially addressed in [18], but for offline monitoring. In [21], the authors design a method for monitoring safety properties in distributed systems using the past-time linear temporal logic (PLTL). In such a work, however, the valuation of some predicates and properties may be overlooked. This is because monitors gain knowledge about the state of the system by piggybacking on the existing communication among processes. That is, if processes rarely communicate, then monitors exchange little information and, hence, some violations of properties may remain undetected. Runtime verification of LTL for synchronous distributed systems where processes share a single global clock has been studied in [6,9]. In [7], the authors introduce parallel algorithms for runtime verification of sequential programs. As already mentioned, our work is inspired by the research line of [11–13], the first one to study the effects of monitor failures in distributed RV. Distributed applications that can be runtime monitored with three opinions were studied in [12], and the number of opinions needed to runtime monitor set agreement was analyzed in [11]. More generally, [13] proves a tight lower bound on the number of opinions needed to monitor a property based on its alternation number. The goal of this paper is to give a formal semantics to the opinions studied in [11–13], and derive a framework in the actual formal context of runtime verification.

**2 Background: Linear Temporal Logics for RV**

Let \(AP\) be a set of *atomic propositions* and \(\Sigma = 2^{AP}\) be the set of all possible states. A *trace* is a sequence \(s_0s_1\cdots\), where \(s_i \in \Sigma\) for every \(i \geq 0\). We denote by \(\Sigma^*\) (resp., \(\Sigma^\omega\)) the set of all finite (resp., infinite) traces. Throughout the paper, we denote infinite traces by the letter \(\alpha\), and finite traces by the letter \(\alpha\). We denote the empty trace by \(\epsilon\). For a finite trace \(\alpha = s_0s_1\cdots s_n\), \(|\alpha|\) denotes its length, i.e., its number of states \(n + 1\). Finally, by \(\alpha^i\), we mean trace \(s_is_i+1\cdots s_n\) of \(\alpha\). We assume that the syntax and semantics of standard LTL is common knowledge. For the reader’s convenience, they are presented in Appendix A.

**Example.** We use the following request/acknowledgment LTL formula throughout the paper to explain the concepts: \(\varphi_{ra} = G(\neg a \land \neg r) \lor ([\neg a U r) \land Fa]\). That is (1) if a request is emitted (i.e., \(r = true\)), then it should eventually be acknowledged (i.e., \(a = true\)), and (2) an acknowledgment happens only in response to a request.

**Finite LTL (FLTL).** In the context of runtime verification, the semantics of LTL is not fully appropriate as it is defined over infinite traces. Finite LTL (FLTL, see [15]) allows us to reason about finite traces for verifying properties at run time. The syntax of FLTL is identical to that of LTL and the semantics is based on the truth values \(\mathbb{B}_2 = \{\top, \bot\}\). The semantics of FLTL for atomic propositions and Boolean operators are identical to those of LTL. We now recall the semantics of FLTL for the temporal operators. Let \(\varphi, \varphi_1\), and \(\varphi_2\) be LTL formulas, \(\alpha = s_0s_1\cdots s_n\) be a non-empty finite trace, and \(|=\text{F}\) denote satisfaction
in FLTL. We have

$$\alpha \models_{F} X \varphi = \begin{cases} \{ \alpha^1 \models_{F} \varphi \} & \text{if } \alpha^1 \neq \epsilon \\ \bot & \text{otherwise} \end{cases}$$

and

$$\alpha \models_{F} \varphi_1 U \varphi_2 = \begin{cases} \top & \text{if } \exists k \in [0,n] : ([\alpha^k \models_{F} \varphi_2] = \top) \land (\forall \ell \in [0,k), [\alpha^\ell \models_{F} \varphi_1] = \top) \\ \bot & \text{otherwise} \end{cases}$$

To illustrate the difference between LTL and FLTL, let $$\varphi = \mathcal{P}_p$$ and $$\alpha = s_0s_1 \cdots s_n$$. If $$p \in s_i$$ for some $$i \in [0,n]$$, then we have $$\alpha \models_{F} \varphi = \top$$. Otherwise, $$\alpha \models_{F} \varphi = \bot$$, and this holds even if the program under inspection extends $$\alpha$$ in the future to a state where $$p$$ becomes true.

**Multi-valued LTLs.** As illustrated above, for a finite trace $$\alpha$$, FLTL ignores the possible future extensions of $$\alpha$$, when evaluating a formula. 3-valued LTL ($$\text{LTL}_3$$, see [5]) evaluates LTL formulas for finite traces with an eye on possible future extensions. In $$\text{LTL}_3$$, the set of truth values is $$\mathbb{B}_3 = \{ \top, \bot, ? \}$$, where ‘$$\top$$’ (resp., ‘$$\bot$$’) denotes that the formula is permanently satisfied (resp., violated), no matter how the current execution extends, and ‘$$?$$’ denotes an unknown verdict; i.e., there exist an extension that can falsify the formula, and another extension that can truthify the formula.

Now, let $$\alpha \in \Sigma^*$$ be a non-empty finite trace. The truth value of an $$\text{LTL}_3$$ formula $$\varphi$$ with respect to $$\alpha$$, denoted by $$[\alpha \models_{3} \varphi]$$, is defined as follows:

$$[\alpha \models_{3} \varphi] = \begin{cases} \top & \text{if } \forall \sigma \in \Sigma^w : \alpha \sigma \models \varphi \\ \bot & \text{if } \forall \sigma \in \Sigma^w : \alpha \sigma \not\models \varphi \\ ? & \text{otherwise.} \end{cases}$$

RV-LTL [4], which we will denote in this paper $$\text{LTL}_4$$, refines the truth value $$?$$ into $$\bot_p$$ and $$\top_p$$. That is, $$\mathbb{B}_4 = \{ \top, \top_p, \bot_p, \bot \}$$. More specifically, evaluation of a formula in $$\text{LTL}_4$$ agrees with $$\text{LTL}_3$$ if the verdict is $$\bot$$ or $$\top$$. Otherwise, (i.e., when the verdict in $$\text{LTL}_3$$ is $$?$$), $$\text{LTL}_4$$ utilizes FLTL to compute a more refined truth value.

Now, let $$\alpha \in \Sigma^*$$ be a finite trace. The truth value of an $$\text{LTL}_4$$ formula $$\varphi$$ with respect to $$\alpha$$, denoted by $$[\alpha \models_{4} \varphi]$$, is defined as follows:

$$[\alpha \models_{4} \varphi] = \begin{cases} \top & \text{if } [\alpha \models_3 \varphi] = \top \\ \bot & \text{if } [\alpha \models_3 \varphi] = \bot \\ \top_p & \text{if } [\alpha \models_3 \varphi] = ? \land [\alpha \models_{F} \varphi] = \top \\ \bot_p & \text{if } [\alpha \models_3 \varphi] = ? \land [\alpha \models_{F} \varphi] = \bot \end{cases}$$

The $$\text{LTL}_4$$ monitor of a formula $$\varphi$$ is the unique deterministic finite state machine $$\mathcal{M}_\varphi^\top = (\Sigma, Q, q_0, \delta, \lambda)$$, where $$Q$$ is a set of states, $$q_0$$ is the initial state, $$\delta : Q \times \Sigma \rightarrow Q$$ is the transition function, and $$\lambda : Q \rightarrow \mathbb{B}_4$$, is a function such that:

$$\lambda(\delta(q_0, a)) = [\alpha \models_{4} \varphi]$$

for every finite trace $$\alpha \in \Sigma^*$$. In [5], the authors introduce an algorithm that takes as input an LTL formula and constructs as output an $$\text{LTL}_4$$ monitor. For example, Fig. 1 shows the $$\text{LTL}_4$$ monitor for the request/acknowledgement formula $$\varphi_{ra} = \mathcal{G}(\neg a \land r) \lor [\neg a U r] \land \mathcal{F}a$$.  

![Figure 1](#)
3 Distributed Runtime Monitoring and Insufficiency of LTL4

In this section, we present a general computation model for asynchronous distributed wait-free monitoring. Throughout the rest of the paper, the system under inspection produces a finite trace $\alpha = s_0s_1\cdots s_k$, and is inspected with respect to an LTL formula $\varphi$ by a set $\mathcal{M} = \{M_1, M_2, \ldots, M_n\}$ of asynchronous distributed wait-free monitors.

Algorithm sketch: For every $j \in [0, k - 1]$, between each $s_j$ and $s_{j+1}$, each monitor, in a wait-free manner:

1. reads the value of propositions in $s_j$, which may result in a partial observation of $s_j$;
2. repeatedly communicates its partial observation with other monitors through a single-writer/multi-reader shared memory;
3. updates its knowledge resulting from the aforementioned communication, and
4. evaluates $\varphi$ and emits a verdict from $\mathbb{B}_4$.

Since each monitor observes and maintains only a partial view of $s_j$, and since the monitors run asynchronously, different read/write interleavings are possible, where each interleaving may lead to a different collective set of verdicts emitted by the monitors in $\mathcal{M}$ for $s_j$. In Subsection 3.1, we formally introduce our notion of wait-free distributed monitoring.

To ensure consistent distributed monitoring, one has to be able to map a collective set of verdicts of monitors (for any execution interleaving) to one and only one verdict of a centralized monitor that has the full view $s_j$. A necessary condition for this mapping is that, for every two finite traces $\alpha, \alpha' \in \Sigma^*$, if $[\alpha \models F \varphi] \neq [\alpha' \models F \varphi']$, then the monitors in $\mathcal{M}$ should compute different collective sets of verdicts for $\alpha$ and $\alpha'$, no matter what their initial partial observation and subsequent read/write interleavings are. We call this condition global consistency, described in detail in Subsection 3.2.

3.1 Wait-Free Distributed Monitoring

We consider a set $\mathcal{M} = \{M_1, M_2, \ldots, M_n\}$ of monitors, each observing a system under inspection. We assume that each monitor in $\mathcal{M}$ has only a partial view of the system under inspection.

▶ Definition 1. A partial state is a mapping $S$ from the set $AP$ of atomic propositions to the set $\{\text{true}, \text{false}, \underline{?}\}$, where $\underline{?}$ denotes an unknown value.

When a state $s$ is reached in a finite trace, each monitor $M_i \in \mathcal{M}$, for $1 \leq i \leq n$, takes a sample from $s$, which results in obtaining a partial state. More formally:

▶ Definition 2. A sample of a state $s \in \Sigma$ by monitor $M_i$ is a partial state $S_i^s$ such that, for all $ap \in AP$, we have: $(S_i^s(ap) = \text{true} \rightarrow ap \in s) \land (S_i^s(ap) = \text{false} \rightarrow ap \notin s)$.

Definition 2 entails that, in a sample, if the value of an atomic proposition is not unknown, then the sampled value is consistent with state $s$. Thus, two monitors $M_i$ and $M_j$ cannot take inconsistent samples. That is, for any state $s$ and samples $S_i^s$, $S_j^s$, and for every $ap \in AP$, we have: $(S_i^s(ap) \neq S_j^s(ap)) \rightarrow (S_i^s(ap) = \underline{?} \lor S_j^s(ap) = \underline{?})$.

We say that a set of monitors cover a state if the collection of partial views of these monitors covers the value of the all atomic propositions. Formally:

▶ Definition 3. A set $\mathcal{M} = \{M_1, M_2, \ldots, M_n\}$ satisfies state coverage for a state $s$ if and only if for every $ap \in AP$, there exists $M_i \in \mathcal{M}$ such that $S_i^s(ap) \neq \underline{?}$. 

CONCUR 2016
Decentralized Asynchronous Crash-Resilient Runtime Verification

**Algorithm 1:** Behavior of Monitor $M_i$, for $i \in [1, n]$

```plaintext
Data: LTL formula $\varphi$ and state $s_j$
Result: a verdict from $\mathbb{B}_4$
1. initialize all elements of $LS_i[j]$ with $\sharp$;
2. $LS_i[j] \leftarrow S_i^j$; /* take sample from state $s_j$ */
3. for some fixed number of rounds do
   4. $SM_i[j] \leftarrow p(LS_i[j])$; /* write (i.e., project) current knowledge in shared memory */
   5. $LS_i[j] \leftarrow SM_i[j]$: /* take a snapshot of the shared memory */
   6. emit $[x(\text{LS}_i[0]) \ldots x(\text{LS}_i[l])] \models \varphi$; /* evaluate $\varphi$ using extrapolation function */
```

Each monitor $M_i$ in $M$ is a process, and the monitors run in the standard asynchronous wait-free read/write shared memory model [3]. Each monitor (1) runs at its own speed, that may vary along with time and (2) may fail by crashing (i.e., halt and never recover). We assume that up to $n - 1$ monitors can crash, and thus a monitor never “waits” for another monitor (since this may cause a livelock). Every monitor that does not fail is required to output; i.e., to emit a verdict. Hence, a distributed algorithm in this settings consists for each monitor in a bounded sequence of read/write accesses to the shared memory at the end of which a verdict is emitted. If the number of possible inputs is bounded, the lengths of such sequences are globally bounded. We thus assume without loss of generality that each monitor accesses the shared memory a fixed number of times before emitting a verdict [14].

More specifically, for every state $s_j$ in $\alpha = s_0s_1\cdots s_k$, each monitor $M_i$ maintains a so-called local snapshot $LS_i[j]$ consisting of $n$ registers, one per monitor in $M$ (i.e., the local snapshot is organized as an array of registers). We denote by $LS_i[j]$ the local register of monitor $M_i$ associated with monitor $M_j$ for state $s_j$. Each register has $|AP|$ elements, one for each atomic proposition in $AP$. The monitors in $M$ communicate by means of shared memory. The structure of the shared memory $SM$ is similar to monitor local snapshots: for each state $s_j$, $SM[j]$ consists of $n$ atomic registers, one per monitor, and each register has $|AP|$ elements one for each atomic proposition (i.e., single-writer/multiple-reader (SWMR) registers). Thus, for state $s_j$, each monitor $M_i$ can read the entire content of $SM[j]$, but can only write into register $SM_i[j]$.

**The distributed monitoring algorithm.** Each monitor $M_i \in M$, $i \in [1, n]$, runs Algorithm 1 that we shall now describe in detail. For any given new state $s_j$, Monitor $M_i$ first initializes all registers of its local snapshot to $\sharp$ (cf. Line 1). Then, $M_i$ takes a sample from state $s_j$ (cf. Line 2). Recall from Def. 2 that the value of an atomic proposition in a sample is either true, false, or $\sharp$. The set of values in the sample is copied in local register $LS_i[j]$. After sampling, each monitor $M_i$ executes a sequence of write/snapshot actions (cf. Lines 4 and 5) for some a priori known number of times, that we detail next.

In Line 4, $M_i$ computes its knowledge about each proposition $ap$, given its content of $LS_i[j]$, and atomically writes it into its associated register $SM_i[j]$ in the shared memory. Function $p = (p_{ap})_{ap \in AP}$ where $p_{ap} : \{true, false, \sharp\}^n \rightarrow \{true, false, \sharp\}$ is the projection

---

1. We assume that each monitor is aware of the change of state of the system under inspection. Thus, for a state $s_j$, a monitor $M_i$ reads and writes in the associated local and shared memory locations, i.e., $LS_i[j]$ and $SM_i[j]$.
2. Algorithm 1 uses snapshot operations for the sake of simplifying the presentation. We emphasize that atomic snapshots can be implemented using atomic read/write operations in a wait-free manner [1].
Given a local snapshot \( LS_i \), \( p(LS_i) \) denotes the partial state obtained by applying \( p_{ap} \) to \( n \) values of each atomic proposition \( ap \) in \( LS_i \). Notice that, based on Definition 2, \( p \) cannot receive contradicting values for an atomic proposition.

In Line 5, \( M_i \) reads all the registers in \( SM[j] \), and copies them into \( LS_i[j] \), in a single atomic step. Finally, after a certain number of iterations, the for-loop ends, and \( M_i \) evaluates \( \varphi \) and emits a verdict based on the content of its local snapshots \( LS_i[0] \cdots LS_i[j] \) (cf. Line 6). To evaluate \( \varphi \) on \( s_0s_1 \cdots s_j \), monitor \( M_i \) needs to compute one and only one Boolean value for each atomic proposition. To this end, we assume that for each atomic proposition \( ap \in AP \), all monitors are provided with the same extrapolation function \( x_{ap} \) allowing them to associate a Boolean value to each atomic proposition, even if its truth value is unknown at some monitors. Such an extrapolation function must satisfy the following consistency condition.

**Definition 4.** Given \( ap \in AP \), a function \( x_{ap} : \{true, false, \top\}^n \to \{true, false\} \) is an extrapolation function if and only if \( p_{ap}(v_1, \ldots, v_n) \neq \top \to x_{ap}(v_1, \ldots, v_n) = p_{ap}(v_1, \ldots, v_n) \).

Given a local snapshot array \( LS \), \( x(LS) \) denotes the state obtained by applying \( x_{ap} \) to \( n \) values of each atomic proposition \( ap \) in \( LS \). Also given a state \( s_j \), by \( [LS[j]] \), we mean the local snapshot of monitor \( M_i \) obtained after termination of the for loop in Algorithm 1.

**Example.** Let \( M = \{M_1,M_2\} \) and consider the formula for two requests and acknowledgments:

\[
\varphi_{r_{a2}} = (G(\neg a_1 \land \neg r_1) \lor (\neg a_1 \lor r_1) \land F a_1) \land (G(\neg a_2 \land \neg r_2) \lor (\neg a_2 \lor r_2) \land F a_2)
\]

Fig. 2 shows different execution interleavings of monitors \( M_1 \) and \( M_2 \) when running Algorithm 1 from states \( s_0 = \{r_1,a_1\} \) and \( s_0' = \{r_1,a_1,r_2\} \). Based on the order of monitor write-snapshot actions: \( M_1,M_2 \) (resp., \( M_2,M_1 \)) denotes the case where monitor \( M_1 \) (resp., \( M_2 \)) executes a write-snapshot before monitor \( M_2 \) (resp., \( M_1 \)) does, and \( M_1|M_2 \) denotes the case where monitors \( M_1 \) and \( M_2 \) execute their write-snapshot actions concurrently. In case of \( s_0 \), after executing Line 2 of Algorithm 1, monitor \( M_1 \)'s sample, i.e., the local snapshot \( LS_1[0] \), consists of \( S_1^{a_1}(r_1) = true, S_1^{a_1}(a_1) = \top \), and \( S_1^{a_2}(r_2) = S_1^{a_2}(a_2) = false \). Moreover, initially, monitor \( M_1 \) has no knowledge of \( M_2 \)'s sample. Monitor \( M_2 \)'s sample from \( s_0' \), i.e., the local snapshot \( LS_2[0] \), consists of \( S_2^{a_1}(r_1) = S_2^{a_1}(a_1) = true, S_2^{a_2}(r_2) = \top \), and \( S_2^{a_2}(a_2) = false \) while it initially has no knowledge of \( M_1 \)'s sample. Likewise, for state \( s_0' \), Fig. 2 shows different local snapshots by \( M_1 \) and \( M_2 \). Given two values \( v_1 \) and \( v_2 \), we define (an arbitrary) extrapolation function as follows:

\[
x_{ap}(v_1,v_2) = \begin{cases} true & \text{if } (v_1 = true) \lor (v_2 = true) \\ false & \text{otherwise} \end{cases}
\]

where \( ap \in \{a_1,r_1,a_2,r_2\} \). Finally, starting from \( s_0 \), if (1) the for loop of Algorithm 1 terminates after 1 communication round, and (2) the interleaving is \( M_1,M_2 \), then \( x([LS_2[0]]) = \{r_1,a_1\} \), and evaluation of \( \varphi_{r_{a2}} \) by \( M_2 \) in \( \LTLfour \) results in \( [x([LS_2[0]])] \models \varphi_{r_{a2}} = \top \).
Definition 5. A monitor trace in \( \text{LTL}_4 \) for \( \alpha \) is a sequence \( m = m_0m_1\cdots m_k \), where, for every \( j \in [0,k] \), \( m_j \subseteq \mathbb{B}_4 \), and each element of each \( m_j \) is the verdict of some monitor \( M_i \in \mathcal{M} \) by evaluating \( [x([LS_i(0)])]x([LS_i(1)])\cdots x([LS_i(j)]) \models_4 \varphi \). For example, Fig. 3, shows a concrete finite trace \( \alpha \) and its corresponding monitor trace.

Definition 6. Let \( \varphi \) be an \( \text{LTL} \) formula, \( \alpha \) be a finite trace in \( \Sigma^* \), and \( m \) be any of its monitor traces. We say that \( m \) satisfies global consistency in \( \text{LTL}_4 \) iff there exists a function \( \mu : 2^{\mathbb{B}_4} \to \{ \top, \bot \} \) such that \( \mu(m_{|\alpha|-1}) = [\alpha \models_\varphi] \).

We now show that \( \text{LTL}_4 \) is unable to consistently monitor all \( \text{LTL} \) formulas. To see this, observe that in Fig. 2, the shaded collective verdicts \( \varphi_{\text{ra}2} \) and \( \varphi_{\text{ra}2} \) from two different states \( s_0 \) and \( s_0' \).

3.2 Global Consistency

For any state \( s_j \), when a set of monitors execute Algorithm 1, different interleavings, and hence different sets of verdicts, are possible. Global consistency is the property enabling to map the set of verdicts of the distributed monitors to the verdict of a centralized monitor that has the full view of states.

Figure 2: Example: Monitors \( M_1 \) and \( M_2 \) monitoring formula \( \varphi_{\text{ra}2} \) from two different states \( s_0 \) and \( s_0' \).
but \([s_0 |\models F \varphi_{r,2} ] \neq [s'_0 |\models F \varphi]\). This clearly does not meet global consistency (see the proof of Lemma 7 for details).

\[\textbf{Lemma 7.} \text{ Not all LTL formulas can be consistently monitored by a 1-round distributed monitor with traces in LTL}_4, \text{ even if monitors satisfy state coverage, and even if no monitors crash during the execution of the monitor.}^{3}\]

Lemma 7 holds for an arbitrary number of communication rounds as well. Indeed, additional rounds of communication will not result into reaching global consistency. This impossibility result is a direct consequence of the main lower bound in [13], which can be rephrased as follows.

\[\textbf{Theorem 8.} \text{ Not all LTL formulas can be consistently monitored by a distributed monitor with traces in LTL}_4, \text{ even if monitors satisfy state coverage, even if no monitors crash during the execution of the monitor, and even if the monitors perform an arbitrarily large number of communication rounds.}\]

In the next section, we revisit the notion of \textit{alternation number} introduced in [13] in order to identify formulas that can be monitored by LTL\(_{4}\), and to design a multi-valued logic to monitor LTL formulas that cannot be monitored in LTL\(_{4}\).

\section{4 Alternation Number}

We now define the notion of \textit{alternation number} [13] in the context of LTL. In the next section, we shall show that the alternation number essentially determines an upper bound on the number of truth values needed to ensure consistency in distributed monitoring.

Let \(\alpha \in \Sigma^*\) be a finite trace, \(\alpha'\) be the longest proper prefix of \(\alpha\), and \(\varphi\) be an LTL formula. We set the \textit{alternation number} of \(\varphi\) with respect to \(\alpha\) as follows:

\[\text{AN}(\varphi, \alpha) = \begin{cases} 0 & \text{if } |\alpha| = 1 \\ \text{AN}(\varphi, \alpha') + 1 & \text{if } (|\alpha| \geq 2) \land (|\alpha' | = \varphi \neq |\alpha | = \varphi) \\ \text{AN}(\varphi, \alpha') & \text{otherwise} \end{cases} \]

---

\(^3\) All proofs appear in Appendix B.
The alternation number with respect to infinite traces is defined as follows. Let \( \sigma \in \Sigma^\omega \) be an infinite trace. If for any prefix \( \alpha \) of \( \sigma \), there exists a finite extension \( \alpha' \), such that \( AN(\varphi, \alpha') < AN(\varphi, \alpha) \), then we set \( AN(\varphi, \sigma) = \infty \). Otherwise, we set \( AN(\varphi, \sigma) = AN(\varphi, \alpha) \) where \( \alpha \) is such that there does not exist a finite extension \( \alpha' \) of \( \alpha \) such that \( AN(\varphi, \alpha') < AN(\varphi, \alpha) \).

Finally, the alternation number of \( \varphi \) with respect to a (possibly infinite) set \( A \) of traces is

\[
AN(\varphi, A) = \max \{ AN(\varphi, \alpha) \mid \alpha \in A \}
\]

**Definition 9.** The alternation number of an LTL formula \( \varphi \) is \( AN(\varphi) = AN(\varphi, \Sigma^*) \).

**Examples.** We have \( AN(Gp) = 1 \) because, in any finite trace \( \alpha \), if the valuation of \( Gp \) in \( \text{Fltl} \) changes from \( \top \) to \( \bot \), then, in no extension of \( \alpha \) this value can change back to \( \top \). We have \( AN(G(r \rightarrow Fa)) = \infty \), because any occurrence of \( r \land \neg a \) evaluates the formula to \( \bot \), and a subsequent occurrence of \( a \) evaluates the formula to \( \top \) in \( \text{Fltl} \). We have \( AN(\varphi_{ra}) = AN(G(\neg a \land \neg r) \lor ([\neg a U r] \land Fa)) = 2 \). Indeed, as long as \( r \land \neg a \) is true throughout a trace \( \alpha \), we have \([\alpha \models_F \varphi_{ra}] = \top\). When \( r \land \neg a \) becomes true, the valuation of \( \varphi_{ra} \) changes to \( \bot \). If \( a \) becomes true subsequently, then \( \varphi_{ra} \) evaluates to \( \top \). By the same type of arguments, we show \( AN(\varphi_{ra}) = 4 \).

Interestingly, the alternation number of an LTL formula \( \varphi \) can be determined from the structure of its LTL\(_4\) monitor automaton \( M^\varphi_i \).

**Theorem 10.** Let \( \varphi \) be an LTL formula. The alternation number of \( \varphi \), \( AN(\varphi) \), is equal to the length of the longest alternating walk in its LTL\(_4\) monitor \( M^\varphi_i \).

**Example.** Let \( \varphi_{ra} = G(\neg a \land \neg r) \lor ([\neg a U r] \land Fa) \). We have \( AN(\varphi_{ra}) = 2 \), and one can check on Fig. 1 that indeed the length of the longest alternating walk in \( M^\varphi_i \) is 2.

## 5 Multi-Valued LTL for Consistent Distributed Monitoring

In this section, we introduce a family of multi-valued logics (called LTL\(_{2k+4}\)), for every \( k \geq 0 \), and relate it to the notion of alternation number. For every \( k \geq 0 \), the syntax of LTL\(_{2k+4}\) is identical to that of LTL. We present the semantics, monitor synthesis, and proof of global consistency of LTL\(_{2k+4}\) in Subsections 5.1, 5.2, and 5.3, respectively.

### 5.1 Semantics of LTL\(_{2k+4}\)

**Truth values.** The semantics of LTL\(_{2k+4}\) refines LTL\(_4\). LTL\(_{2k+4}\) employs the following set of \( 2k + 4 \) truth values:

\[
B_{2k+4} = \{ \bot, \top, \bot_0, \ldots, \bot_k, \top_0, \ldots, \top_k \}.
\]

Intuitively, for \( i \in [0, k] \), truth value \( \bot_i \) means *possibly false* with *degree of certainty* \( i \), and truth value \( \top_i \) means *possibly true* with degree of certainty \( i \), while \( \top \) and \( \bot \) have the same meaning as their LTL\(_3\) counterparts. Thus, LTL\(_{2k+4}\) coincides with LTL\(_4\) for \( k = 0 \). Consider a non-empty finite trace \( \alpha = s_0s_1 \cdots s_n \) in \( \Sigma^* \). We denote the valuation of a formula \( \varphi \) with respect to \( \alpha \) in LTL\(_{2k+4}\) by \([\alpha \models_{2k+4} \varphi] \). Since, for any \( i \in [0, k] \), \( \bot_i \) implies ‘?’ in LTL\(_3\), we require that \([\alpha \models_{2k+4} \varphi] = \bot_i \rightarrow [\alpha \models_{3} \varphi = ? \land [\alpha \models_F \varphi] = \bot \). The latter conjunct is to relate \( \bot_i \) with the valuation of \( \alpha \) in FLTL. Likewise, we require that, for any \( i \in [0, k] \):

\[
[\alpha \models_{2k+4} \varphi] = \top_i \rightarrow [\alpha \models_{3} \varphi = ? \land [\alpha \models_F \varphi] = \top \). We determine the degree of certainty of \([\alpha \models_{2k+4} \varphi] \) inductively according to the judgment rules below, where \( \alpha' = s_0s_1 \cdots s_{n-1} \).
Observe that the degree of certainty does not change if the Fltl valuation does not change in \( \alpha' \) and \( \alpha \), or change from \( \perp \) to \( \top \). On the contrary, the degree of certainty does change if the Fltl valuation changes in \( \alpha' \) and \( \alpha \) from \( \top \) to \( \perp \), respectively.

\[
[\alpha \models_{2k+4} \varphi] = \begin{cases} 
\bot & \text{if } [\alpha \models_3 \varphi] = \bot \\
\top & \text{if } [\alpha \models_3 \varphi] = \top \\
\bot_0 & \text{if } [\alpha] = 1 \land [\alpha \models_3 \varphi] = \top \land [\alpha \models_F \varphi] = \bot \\
\top_0 & \text{if } [\alpha] = 1 \land [\alpha \models_3 \varphi] = \top \land [\alpha \models_F \varphi] = \top \\
\bot_i & \text{if } [\alpha] \geq 2 \land [\alpha \models_3 \varphi] = \top \land [\alpha \models_F \varphi] = \bot \land \exists \alpha' \models_{2k+4} \varphi \in \{ T_i, \bot_i \} \\
\top_i & \text{if } [\alpha] \geq 2 \land [\alpha \models_3 \varphi] = \top \land [\alpha \models_F \varphi] = \bot \land \exists \alpha' \models_{2k+4} \varphi \in \{ T_i, \bot_i \} \\
\bot_k & \text{if } [\alpha] \geq 2 \land [\alpha \models_3 \varphi] = \top \land [\alpha \models_F \varphi] = \bot \land \exists \alpha' \models_{2k+4} \varphi \in \{ \bot_k, T_k, \bot_{k-1} \} 
\end{cases}
\]

### 5.2 Monitorability and Monitor Synthesis for LTL\(_{2k+4}\)

Pnueli and Zaks [20] characterize an LTL formula \( \varphi \) as *monitorable* for a finite trace \( \alpha \), if \( \alpha \) can be extended to one that can be evaluated with respect to \( \varphi \) at run time. That is, an LTL formula \( \varphi \) is *monitorable* in LTL\(_4\) if and only if: \( \forall \alpha \in \Sigma^* : \exists \alpha' \in \Sigma^*: [\alpha \alpha'] \models_3 \varphi \neq \top \) We stick to the same definition for LTL\(_{2k+4}\).

**Definition 11.** Let \( \varphi \) be an LTL formula. The LTL\(_{2k+4}\) monitor of \( \varphi \) is the unique deterministic finite state machine \( M_{2k+4}^\varphi = (\Sigma, Q, q_0, \delta, \lambda) \), where \( Q \) is a set of states, \( q_0 \) is the initial state, \( \delta : Q \times \Sigma \to Q \) is the transition function, and \( \lambda : Q \to \mathbb{B}_{2k+4} \), such that, for every non-empty finite trace \( \alpha \in \Sigma^* \), we have \([\alpha \models_{2k+4} \varphi] = \lambda(\delta(q_0, \alpha)) \).

Algorithm 2 constructs LTL\(_{2k+4}\) monitors. Intuitively, our algorithm creates \( k+1 \) copies of LTL\(_4\) monitors by invoking Function \text{ConstructMonitor}, and cascades them in such a way that incrementing the degree of certainty is implemented as prescribed by our definition of LTL\(_{2k+4}\). Observe that for a given value \( i \in [0, k] \), Function \text{ConstructMonitor} renames truth value \( \top_p \) (respectively, \( \bot_p \)) in LTL\(_4\) to \( \top_i \) (respectively, \( \bot_i \)) (see Lines 14-18). Cascading the monitors in Algorithm 2 is as follows. Initially, we generate an LTL\(_4\) monitor for \( k = 0 \) (Line 1). Then, in each step \( i \in [1, k] \) of the for-loop, we generate a new LTL\(_4\) monitor (cf. Line 3). We ensure incrementing the degree of certainty by removing monitor transitions \((q, a, q')\), where \( q \) is annotated by \( \top_{i-1} \) and \( q' \) is annotated by \( \bot_{i-1} \), and adding transitions \((q, a, \bar{q})\), where \( \bar{q} \) is annotated by \( \bot_i \) (Lines 5-10).

**Algorithm 2:** Monitor construction for LTL\(_{2k+4}\)
Theorem 12. Let \( \varphi \) be an LTL formula, and let \( M^\varphi_{2k+4} = (\Sigma, Q, q_0, \delta, \lambda) \) be its LTL\(_{2k+4}\) monitor such as constructed by Algorithm 2. Then, for any non-empty finite trace \( \alpha \in \Sigma^* \), we have \( \lambda(\delta(q_0, \alpha)) = \alpha \models_{2k+4} \varphi \).

5.3 Monitoring Algorithm and Global Consistency in LTL\(_{2k+4}\)

Monitoring Algorithm. Let \( \alpha = s_0s_1 \cdots s_k \) be a finite trace in \( \Sigma^* \). As discussed in Section 3, for any state \( s_j \), where \( j \in [0, k] \), each monitor runs Algorithm 1 and emits a verdict. In order to employ LTL\(_{2k+4}\) and ensure consistency, each monitor has to compute the highest possible degree of certainty by considering all possible monitor communication interleavings that result in state \( s_j \). Formally, the set of all interleavings that reach a state \( s \in \Sigma \) is the set of sequences of partial states defined as follows:

\[
I_s = \{ S_0S_1 \cdots S_l \mid (\forall ap \in AP : S_0(ap) = \perp) \land (S_l = s) \land (\forall i \in [0, l] : S_i(ap) \neq \perp) \rightarrow (\forall m \in (i, l] : S_i(ap) = S_m(ap)) \}
\]

Now, for state \( s_j \) in \( \alpha \) and formula \( \varphi \), a monitor \( M_i \) computes \( AN(\varphi, I_{\alpha[J]}(\Sigma_{s_i[j]})) \). This can be done by running each trace in \( I_{\alpha[J]}(\Sigma_{s_i[j]})) \) on the LTL\(_{2k+4}\) monitor of \( \varphi \). This is indeed the key idea to ensure global consistency.

Observation 13. For any state \( s \in \Sigma \) and LTL formula \( \varphi \), we have \( AN(\varphi, I_s) \leq AN(\varphi) \).

Example. Fig. 4 shows how monitors \( M_1 \) and \( M_2 \) evaluate formula \( \varphi_{ra2} \) in LTL\(_{2k+4}\) with \( k = 2 \). Observe that the two sets of verdicts that were not distinguishable in Fig. 2 (i.e., \( m_0 = m'_0 = \{ \perp, 1 \} \) ) are now distinguishable (i.e., \( m_0 = \{ \perp, 1 \} \), while \( m'_0 = \{ 1, \perp \} \)), as we are now using 8 truth values instead of just 4. The ability of monitoring a formula in LTL\(_{2k+4}\) for a given \( k \geq 0 \) is strongly related to the alternation number of the formula.

Main Results. The following identifies an upper-bound on the number of truth values needed to monitor any LTL formula.

Theorem 14. An LTL formula \( \varphi \) can consistently be monitored by a wait-free distributed monitor in LTL\(_{2k+4}\), if

\[
k \geq \lceil \frac{1}{2} \{ \min(AN(\varphi), n) - 1 \} \rceil
\]

where \( n \) is the number of monitors.

An immediate consequence of Theorem 14 is for computing \( \mu \) (Definition 6) for LTL\(_{2k+4}\). For a set \( m \in \Sigma_{2k+4} \), one can compute \( \mu(m) \) by identifying the supremum of \( m \), for the total order \( \perp_0 < \top_0 < \perp_1 < \top_1 < \ldots < \perp_k < \top_k \). It is straightforward to observe that such a \( \mu \) results in global consistency for LTL\(_{2k+4}\). Also, notice that Theorem 14 is best possible. It matches the following generalization of Theorem 8. The proof is similar to the lower bound of [13].

Theorem 15. For each \( k \geq 0 \), there is an LTL formula \( \varphi \) that cannot be consistently monitored by a wait-free distributed monitor in LTL\(_{2k+4}\), if

\[
k < \lceil \frac{1}{2} \{ \min(AN(\varphi), n) - 1 \} \rceil
\]

where \( n \) is the number of monitors.
In this paper, we proposed a family of multi-valued logics $\text{LTL}_{2k+4}$, each one with $2k+4$ truth values, for fault-tolerant distributed RV, refining existing finite $\text{LTL}$ semantics. We presented an idealized setting where a set of unreliable monitors emit consistent verdicts in $\text{LTL}_{2k+4}$ about the correctness of the system under inspection, if $k$ is sufficiently large.

We note that wait-free computing is a powerful and simple abstraction to model and reason about distributed algorithms. All results in this paper can theoretically be transformed to more practical refinements such as message passing frameworks. Of course, further research is needed to develop such transformations. From a more practical perspective, it would be interesting to relax the timing model enabling monitors to observe, communicate, and emit verdicts between any two global states; to study frameworks for message passing systems, and to address more severe, even Byzantine failures.

**Figure 4** Global consistency of $\text{LTL}_{2k+4}$ monitors $M_1$ and $M_2$ for formula $\varphi_{ra_2}$, where $k = 2$.

A Syntax and Semantics of LTL

Syntax. Linear Temporal Logic (LTL) formulas [19] are defined using the following grammar:

\[ \varphi ::= \text{true} \mid \text{ap} \mid \neg \varphi \mid \varphi \lor \varphi \mid \varphi_1 \land \varphi_2 \mid \varphi \rightarrow \psi \mid \varphi \lor \psi \mid \varphi \land \psi \mid \varphi_1 \land \varphi_2 \mid \varphi_1 \lor \varphi_2 \]

where \( \text{ap} \in AP \), and, \( \text{X} \) (next) and \( \text{U} \) (until) are temporal operators. We view other propositional and temporal operators as abbreviations, that is, \( \text{false} = \neg \text{true} \), \( \varphi \rightarrow \psi = \neg \varphi \lor \psi \), \( \varphi \land \psi = \neg (\neg \varphi \lor \neg \psi) \), \( \text{F} \varphi = \text{true} \lor \varphi \) (finally \( \varphi \)), and \( \text{G} \varphi = \neg \text{F} \neg \varphi \) (globally \( \varphi \)).

Semantics. The traditional infinite-trace semantics of LTL is defined as follows. Let \( \sigma = s_0s_1 \cdots \in \Sigma^\omega \), let \( i \geq 0 \), and let \( \models \) denote the satisfaction. We have:

\[ \sigma, i \models \varphi \iff \text{true} \]
\[ \sigma, i \models \text{ap} \iff \text{ap} \in s_i \]
\[ \sigma, i \models \neg \varphi \iff \sigma, i \not\models \varphi \]
\[ \sigma, i \models \varphi_1 \lor \varphi_2 \iff \sigma, i \models \varphi_1 \text{ or } \sigma, i \models \varphi_2 \]
\[ \sigma, i \models \varphi \rightarrow \psi \iff \sigma, i + 1 \models \varphi \]
\[ \sigma, i \models \varphi_1 \lor \varphi_2 \iff \exists k \geq i : \sigma, k \models \varphi_2 \text{ and } \forall j \in [i, j) : \sigma, j \models \varphi_1. \]

Also, \( \sigma \models \varphi \) holds if and only if \( \sigma, 0 \models \varphi \) holds.

B Proofs

Lemma 7. Not all LTL formulas can be consistently monitored by a 1-round distributed monitor with traces in \( \text{LTL}_4 \), even if monitors satisfy state coverage, and even if no monitors crash during the execution of the monitor.

Proof. An immediate consequence of Definition 6 is that, for any two finite traces \( \alpha, \alpha' \in \Sigma^* \) and their corresponding monitor traces \( m, m' \in (2^B)^* \), we must have:

\[ [\alpha \models \varphi] \neq [\alpha' \models \varphi] \rightarrow \mu(m|_{\alpha|-1}) \neq \mu(m'|_{\alpha'}|-1). \]

We show that there exist an LTL formula \( \varphi \), finite traces \( \alpha, \alpha' \in \Sigma^* \), and their monitor traces \( m \) and \( m' \) in \( \text{LTL}_4 \), such that

\[ [\alpha \models \varphi] \neq [\alpha' \models \varphi] \text{ and } m|_{\alpha|-1} = m'|_{\alpha'}|-1, \]

even if monitors satisfy state coverage and are not subject to crash faults. For this purpose, let us consider the LTL request/acknowledgement formula \( \varphi_{ra2} \), and traces \( \alpha = s_0 \) and \( \alpha' = \]
s₀ as in Fig. 2. If the monitors decide to emit a verdict after one round of communication, then let us consider the following scenarios:

Scenario 1: Starting from state s₀ with M₁, M₂ interleaving, we have \( [x(LS_0[0]) \models F \varphi_{r_{a_2}}] = \bot \) and \( [x(LS_2[0]) \models F \varphi_{r_{a_2}}] = \top \). That is, the collective set of local verdicts is \( m₀ = \{\bot, \top\} \).

Scenario 2: Starting from state s₀, with M₂, M₁ interleaving, we have \( [x(LS'_1[0]) \models F \varphi_{r_{a_2}}] = \bot \) and \( [x(LS'_2[1]) \models F \varphi_{r_{a_2}}] = \top \). That is, the collective set of local verdicts is \( m₀' = \{\bot, \top\} \).

Therefore, although the valuation of \( \varphi_{r_{a_2}} \) for two finite traces \( \alpha \) and \( \alpha' \) are different in Fltl (i.e., \( \top \) and \( \bot \), respectively), the collective set of verdicts emitted by monitors M₁ and M₂ in the above two scenarios are identical (i.e., \( \{\bot, \top\} \)). That is,

\[
[\alpha \models F \varphi_{r_{a_2}}] \neq [\alpha' \models F \varphi_{r_{a_2}}],
\]

but \( \mu(m₀) = \mu(m₀') \) for any \( \mu \). Hence, global consistency is violated. ▫

Theorem 10. Let \( \varphi \) be an Ltl formula. The alternation number of \( \varphi \), \( AN(\varphi) \), is equal to the length of the longest alternating walk in its Ltl₄ monitor \( M₄^\varphi \).

Proof. First, note that no states of \( M₄^\varphi \) labeled by \( \bot \) or \( \top \) can reach other states, as these truth values denote permanent violation and satisfaction, respectively. We consider two cases.

Let us assume first that \( AN(\varphi) = \infty \). Then there exists \( \sigma \in \Sigma^\omega \), where throughout \( \sigma \), valuation of formula \( \varphi \) in Fltl alternates infinitely many times. Indeed, according to Definition 9, for every finite trace \( \alpha \), there exists finite trace \( \alpha' \), such that \( \alpha \) is a prefix of \( \alpha' \) and \( [\alpha \models F \varphi] \neq [\alpha' \models F \varphi] \). Since \( M₄^\varphi \) respects the semantics of Ltl₄, and since it has only a finite number of states, it must contain a cycle that includes \( \bot \) and \( \top \). The length of a longest walk in cyclic graph is then infinite.

Let us now assume that \( AN(\varphi) = m < \infty \). This means that there exists \( \alpha \in \Sigma^* \), in which valuation of \( \varphi \) in Fltl alternates \( m \) number of times. Running \( \alpha \) on \( M₄^\varphi \) should result in \( m \) switches from \( \top \) to \( \bot \), and this walk ends in a state labeled by \( \bot \) or \( \top \). Thus, the length of the walk in \( M₄^\varphi \) that runs \( \alpha \) is \( m \). ▫

Theorem 12. Let \( \varphi \) be an Ltl formula, and let \( M_{2k+4}^\varphi = (\Sigma, Q, q₀, \delta, \lambda) \) be its Ltl₂k₊₄ monitor such as constructed by Algorithm 2. Then, for any non-empty finite trace \( \alpha \in \Sigma^* \), we have \( \lambda(\delta(q₀, \alpha)) = [\alpha \models _{2k+4} \varphi] \).

Proof. We prove the theorem by induction on the length of \( \alpha \). So, assume first that \( \alpha = s₀ \). Without loss of generality, let us assume that the initial state of an Ltl₄ monitor constructed by ConstructMonitor is always labeled by \( \top \). We now distinguish the following cases.

- If \( [\alpha \models _{2k+4} \varphi] = \bot \), then \( \delta(q₀, \alpha) \) results in a monitor state \( q \), where \( \lambda(q) = \bot \). This is because if there is a transition \( (q₀, s₀, q) \) in \( M₄^\varphi \), then this transition also exists in \( M_{2k+4}^\varphi \). Since Algorithm 2 does not touch monitor states and transitions that leads to a state where the verdict is \( \bot \), it follows that \( \lambda(q) \) has to be \( \bot \). The proof for the case where \( [\alpha \models _{2k+4} \varphi] = \top \) is identical.

- If \( [\alpha \models _{2k+4} \varphi] = \top \), then \( \delta(q₀, \alpha) \) results in a monitor state \( q \), where \( \lambda(q) = \top \). This is because if there is a transition \( (q₀, s₀, q) \) in \( M₄^\varphi \), then this transition remains intact in the monitor created in Line 1 of Algorithm 2.
If \([\alpha \models_{2k+4} \varphi] = \perp_0\), then \(\delta(q_0, \alpha)\) should result in a monitor state \(q\), where \(\lambda(q) = \perp_0\). This is because if there is a transition \((q_0, s_0, q')\) in \(M^2_{2k+4}\), where \(\lambda(q') = \perp_p\), then since \(\lambda(q_0) = \perp_0\) in \(M^2_{2k+4}\), this transition is removed and a transition to a state \(q\) where \(\lambda(q) = \perp_1\) is added (Lines 5-10) in Algorithm 2.

The proof of the inductive step is identical to the proof of base case except all 0’s are replaced by \(i\) and all 1’s are replaced by \(i + 1\).

**Theorem 14.** An LTL formula \(\varphi\) can consistently be monitored by a wait-free distributed monitor in LTL\(_{2k+4}\), if

\[
k \geq \left\lceil \frac{1}{2} \min(AN(\varphi), n) - 1 \right\rceil
\]

where \(n\) is the number of monitors.

**Proof.** Let \(\alpha\) and \(\alpha'\) be two finite traces in \(\Sigma^*\). In order to show consistent monitoring, we should prove that if \([\alpha \models F \varphi] \neq [\alpha' \models F \varphi]\), then for any two corresponding monitor traces \(m\) and \(m'\), we have \(m_{|\alpha| - 1} \neq m'_{|\alpha'| - 1}\).

Without loss of generality, suppose we have

\([\alpha \models F \varphi] = T\)

and

\([\alpha' \models F \varphi] = \perp\).

We prove this theorem by induction on the length of \(\alpha\) and \(\alpha'\):

- **Base case:** Suppose \(|\alpha| = |\alpha'| = 1\); i.e., \(\alpha = s_0\) and \(\alpha' = s_0'\). When \(s_0\) and \(s_0'\) occur, the monitors execute Algorithm 1, which results in obtaining arbitrary collective verdicts \(m_0\) and \(m_0'\), respectively. Observe that \(m_0\) and \(m_0'\) are not unique and they depend on different interleavings execution of Algorithm 1. In obtaining \(m_0\) (respectively, \(m_0'\)), let \(M_i\) (respectively, \(M'_j\)) be the last monitor that executed Line 6 of Algorithm 1. Since we assume state coverage, we have\(^4\)

\([\alpha \models F \varphi] = [x([LS_i[0]])] \models F \varphi\)

and

\([\alpha' \models F \varphi] = [x([LS_j[0]])] \models F \varphi\).

This is because when monitor \(M_i\) (respectively, \(M'_j\)) takes a snapshot from the shared memory, it observes a full view of state \(s_0\) (respectively, \(s_0'\)) and, hence, its evaluation of \(\varphi\) agrees with a centralized monitor that evaluates \(\varphi\). This implies that in LTL\(_{2k+4}\), we have

\([x([LS_i[0]])] \models K \varphi] = \top_i\)

and

\([x([LS_j[0]])] \models K \varphi] = \perp_{i'}\)

for some \(0 \leq i, i' \leq 2k + 4\) and \(\top_i \in m_0\) and \(\perp_{i'} \in m'_0\). We now prove that the inclusion of \(\top_i\) and \(\perp_{i'}\) in \(m_0\) and \(m_0'\), respectively implies that \(m_0 \neq m_0'\). To this end, first observe that since we assume that \(k \geq \frac{1}{2}(AN(\varphi) - 1)\), we have \(2k + 2 \geq AN(\varphi)\). Thus,

\(^4\) Recall that \([LS_i[0]]\) denote the local snapshot of monitor \(M_i\) obtained after writing/reading the shared memory a certain number of times, as prescribed by algorithm 1.
since truth value ⊥₀ is not needed according to the semantics of LTL₂k₊₄, evaluation of a formula ϕ for a finite trace and in particular, α and α’ never “runs out of” truth values and does not result in saturated verdicts. Now, we distinguish the following cases:

= Case 1 (i < i’): In this case, ⊥ᵢ can not be a member of m₀. This is because a ⊥ᵢ valuation is always obtained by an additional alternation of a ⊤ᵢ₋₁ (in LTL₂k₊₄) to ⊥ᵢ in a trace of Tᵢᵢ. If ⊥ᵢ is in m₀, then [ϕ([LS]₀)] |=ᵢ ϕ must have evaluated to ⊤ᵢ, where i’ > i, which would be a contradiction, since we assumed i’ > i. Hence, m₀ ≠ m’₀.

= Case 2 (i ≥ i’): In this case, ⊤ᵢ can not be a member of m’₀. This is because a ⊤ᵢ valuation is always obtained by an additional alternation of a ⊥ᵢ (in LTL₂k₊₄) to ⊤ᵢ in a trace of Tᵢᵢ. If ⊤ᵢ is in m’₀, then [ϕ([LS]_[i])] |=ᵢ ϕ must have evaluated to ⊥ᵢ’, where i’ > i which would be a contradiction, since we assumed i ≥ i’. Hence, m₀ ≠ m’₀.

= Inductive step: Suppose that we have [s₀s₁⋯sᵢ |=ᵢ LTL ϕ] ≠ [s₀′s₁′⋯sᵢ′ |=ᵢ LTL ϕ] and for any two corresponding monitor traces m and m’, we have mᵢ ≠ m’ᵢ. We need to show that if [s₀s₁⋯sᵢ+1 |=ᵢ LTL ϕ] ≠ [s₀′s₁′⋯sᵢ+1 |=ᵢ LTL ϕ], then mᵢ+1 ≠ m’ᵢ+1. In the base case we showed that LTL₂k₊₄ monitors one state consistently. Thus, LTL₂k₊₄ monitoring of an extended finite trace by one state preserves global consistency.

C Proof of Theorem 15

C.1 The setting

We are going to consider a formula ϕₙ for N requests and acknowledgments, and show that any distributed monitor for ϕₙ in LTL₂k₊₄ that is able to distinguish violating from satisfying global executions at run time, must have k ≥ N − 1. We follow the proof style of [11].

Consider a trace of states xᵢ, satisfying property ϕₙ. Then, for each i, rᵢ appears in some xᵢ implies aᵢ appears in some xᵢ, where m ≥ ℓ. Also, in FtLTL, a finite trace satisfies ϕₙ if and only if, in the last state of the trace, every entry is either ε (no true variables) or equal to rᵢaᵢ for some i.

Consider the following trace, σ₂ₙ, corresponding to what is known about the global state by the monitors. We use a partial order, to denote the situation where the values of more variables is known, W = x₁ ≤ x₂ ≤ ⋯ ≤ x₂ₙ, as follows:

(r₁, ε, ⋯, ε), (r₁a₁, ε, ⋯, ε), (r₁a₁r₂, ⋯, ε), (r₁a₁r₂a₃, ⋯, ε), ⋯, (r₁a₁r₂a₃, ⋯, rₙaₙ).

Intuitively, one monitor may know that rᵢ is true, then another monitor knows also that aᵢ is true, and so on.

We need two properties of this trace.

Observation 16. [ϕ’ |=ᵢ LTL ϕ] = ⊥ if and only if |ϕ’| is odd, for each prefix ϕ’ of σ₂ₙ.

The other property we need is about subtraces of a trace. A subtrace of σ is a trace obtained by removing states from σ. Denote by σ⁽j⁾ the subtrace obtained from σ by projecting out its j – th element. Let σₖ be the prefix of σ₂ₙ of size k.

Observation 17. For each σₖ, it holds
1. $[\sigma_k^{(k)} \models \varphi_N] \neq [\sigma_k \models \varphi_N]$
2. $[\sigma_k^{(j)} \models \varphi_N] = [\sigma_k \models \varphi_N]$, for all $j \neq k$.

Next, we are going to consider an assignment of the monitored variables $V = \{v_1, \ldots, v_n\}$, where the value of $v_1, \ldots, v_n$ corresponds to the values in $\sigma_{2N-1}$. Call this assignment $\tau_n$, and consider another assignment $\tilde{\tau}_n$ which corresponds to $\sigma_{2N}^{(1)}$, which is identical to $\tau_n$ except that $v_1 = \bar{x}_{2N}$. Similarly, define $\tau_j$ and $\tilde{\tau}_j$, as illustrated in Figure 5. We need to view $\tau_n$ and $\tilde{\tau}_n$ as simplexes (sets). Thus, before continuing with the proof in Section C.3, we recall some combinatorial topology notation.

C.2 Topology Framework

We use the same framework of [11] verbatim.

C.2.1 Basic notions of topology

We first review some basic definitions. A complex $\mathcal{K}$ is a set of vertices $V(\mathcal{K})$, and a family of finite, nonempty subsets of $V(\mathcal{K})$, called simplexes, satisfying: (1) if $v \in V(\mathcal{K})$ then $\{v\}$ is a simplex, and (2) if $s$ is a simplex, so is every nonempty subset of $s$. The dimension of a simplex $s$ is $|s| - 1$, the dimension of $\mathcal{K}$ is the largest dimension of its simplexes, and $\mathcal{K}$ is pure of dimension $k$ if every simplex belongs to a $k$-dimensional simplex. A simplex $\tau$ is a face of a simplex $\sigma$ if $\tau$ is a subset of $\sigma$. If $\tau$ is not equal to $\sigma$ then $\tau$ is a proper face of $\sigma$. The complex induced by a simplex $\sigma$ consists in $\sigma$ and all its faces.

In distributed computing, a vertex represents a local state, a simplex a global state and a complex a collection of global states. Hence, one of the labels of each vertex is an identity in $[n]$. We denote by $\text{ID}(\sigma)$ the identities of the vertexes of $\sigma$. A simplex is chromatic if it is properly colored with ids in $[n]$. A complex is chromatic if each of its simplexes is chromatic.

A simplicial map $f$ from complex $\mathcal{K}$ to complex $\mathcal{L}$ is a function from $V(\mathcal{K})$ to $V(\mathcal{K})$ that preserves simplexes. That is, if $\tau = \{v_1, \ldots, v_k\}$ is a simplex of $\mathcal{K}$, then $\{f(v_1), \ldots, f(v_k)\}$ is a simplex of $\mathcal{L}$. In addition, if $\mathcal{K}$ and $\mathcal{L}$ are chromatic complexes, $f$ is said to be id-preserving if for any simplex $\tau = \{v_1, \ldots, v_k\} \in \mathcal{K}$, $\text{ID}(\tau) = \text{ID}(\{f(v_1), \ldots, f(v_k)\})$. 

Figure 5 Inputs for $p_1, p_2, p_3$
C.2.2 Pseudomanifold and divided images

A complex $K$ of dimension $n$ is a pseudomanifold with boundary if it is strongly connected, and each $(n-1)$-simplex in $K$ is a face of precisely one or two $n$-simplexes. For simplicity, a pseudomanifold with boundary will simply be called a pseudomanifold. We sometimes write $n$-pseudomanifold as a shorthand for an $n$-dimensional pseudomanifold. Let $K$ be a $n$-pseudomanifold. A $(n-1)$-simplex $\sigma$ is said to be internal if it is a face of exactly two $n$-simplexes of $K$ and external otherwise. The boundary of $K$, denoted $\partial K$, is the sub-complex of $K$ induced by its external simplexes. More precisely, $\partial K$ consists in each $(n-1)$-simplex of $K$ that is a face of exactly one $n$-simplex together with all its faces.

Divided images of complexes have been introduced in [2] as a combinatorial tool to represent certain classes of executions of read/write wait-free protocols. A subdivision of a complex is a divided image, but subdivided images are not always subdivisions. Divided images capture the essential properties to study wait-free computability.

► Definition 18 ([2], Definition 4.1). Let $K$ and $L$ be finite $n$-dimensional complexes and $\psi$ a function that maps every simplex of $K$ to a subcomplex of $L$. The complex $K$ is a divided image of $L$ under $\psi$ if and only if
1. $\psi(\emptyset) = \emptyset$,
2. for every 0-simplex $\sigma \in L$, $\psi(\sigma)$ is a single vertex,
3. for every $\sigma, \sigma' \in L$, $\psi(\sigma \cap \sigma') = \psi(\sigma) \cap \psi(\sigma')$, and
4. for every $\sigma \in L$, $\psi(\sigma)$ is a $\dim(\sigma)$-pseudomanifold with $\partial \psi(\sigma) = \psi(\partial \sigma)$.

When $\psi$ is clear from the context or not relevant, we simply say that $K$ is a subdivided image of $L$. Next Lemma state some properties of divided:

► Lemma 19 ([2], Lemma 4.2). Let $K, L$ be $n$-dimensional complexes such that $K$ is a divided image of $L$ under $\psi$.
1. For every $\sigma, \sigma' \in L$, if $\sigma \subseteq \sigma'$, then $\psi(\sigma) \subseteq \psi(\sigma')$.
2. For every pair of $j$ simplexes $\sigma, \sigma' \in K$, if $\sigma \neq \sigma'$ and $\sigma \cap \sigma' \neq \emptyset$, then $\psi(\sigma \cap \sigma')$ is a pseudomanifold of dimension strictly smaller than $j$.
3. A $(n-1)$-dimensional simplex $\tau \in K$ is external if and only if for some external $(n-1)$-dimensional simplex $\sigma \in L$, $\tau \in \psi(\sigma)$.

The carrier of simplex $\tau \in K$, denoted $\text{carrier}(\tau)$ is the simplex $\sigma \in L$ of smallest dimension such that $\tau \in \psi(\sigma)$. Note that, by Definition 18(3), $\text{carrier}(\tau)$ is well defined and by Lemma 19(2), it is unique. If $L$ is a chromatic complex, $K$ is a chromatic divided image [2] of $L$ if $K$ is a divided image of $L$, $K$ is a chromatic complex, and for any $\tau \in K$, $\text{ID}(\tau) \subseteq \text{ID}(\text{carrier}(\tau))$. Note in particular that if $\dim(\tau) = \dim(\text{carrier}(\tau))$, $\tau$ is properly colored with the ids in $\text{ID}(\tau)$.

C.2.3 Combinatorial implication of wait-free computability

Simplexes and complexes are a convenient way to represent tasks and distributed protocols. A task $T = (I, O, \Delta)$ can be described by an input complex $I$, an output complex $O$ and a function $\Delta$ that maps each simplex of $I$ to a sub-complex of $O$. Vertices of $I$ and $O$ are labeled with an identity and a value and there is a simplex $s = \{ (id_1, v_1), \ldots, (id_\ell, v_\ell) \}$ in $I$ (respectively, $O$) if and only if $s$ represents a valid assignment of inputs to the processes (respectively, for an output simplex in $O$). Similarly, $t \in \Delta(s)$ if and only if the corresponding output simplex $t$ represents valid outputs of the processes when starting in $s$.

Without loss of generality, a read/write wait-free protocol consists in a certain number $B$ of (asynchronous) rounds. In each round, process $p_i$ writes its state in its cell $R[i]$, takes a
snapshot of the memory and updates its state. The process initial state is its input. At the end of the \( B \) rounds, a final state is reached which includes the process decision. A protocol complex \( \mathcal{P} \) represents all possible final states for each execution. Each vertex is labeled with an id and a possible final state. \( \sigma = \{(id_1, v_1), \ldots, (id_\ell, v_\ell)\} \) is a simplex in \( \mathcal{P} \) if there is an execution at the end of which process \( p_i \) with identity \( id_i \) is in state \( v_i \), for \( 1 \leq i \leq \ell \).

An immediate snapshot execution can be divided into blocks. In each block, a subset of the participating processes are active. They first simultaneously write before taking a snapshot. One important result of the topological approach is a characterization of the immediate snapshot protocol complex is a chromatic divided image of the input complex [2]. If a protocol solves a task \( T = (\mathcal{I}, \mathcal{O}, \Delta) \), in any execution, the final states are mapped to decision values in such a way that the output simplex is allowed for the input simplex of the execution according to \( \Delta \). To derive impossibility results, it is sufficient to consider only a subset of all possible executions. We recall the following necessary condition for read/write wait-free solvability of tasks:

\begin{itemize}
  \item \textbf{Theorem 20} ( [2], Theorem 5.10). Let \( T = (\mathcal{I}, \mathcal{O}, \Delta) \) a task. If there is a read/write wait-free protocol which solves \( T \), then there is a chromatic divided image \( \mathcal{I}^+ \) of \( \mathcal{I} \) and a \( \text{id}-\text{preserving simplicial map} \ (\delta) \) from \( \mathcal{I}^+ \) to \( \mathcal{O} \) that agrees with \( \Delta \).
\end{itemize}

\subsection{A variant of Sperner’s Lemma}

Given a function \( f : V(K) \rightarrow U \), for each simplex \( \sigma = \{v_0, \ldots, v_k\} \) of \( K \), \( f(\sigma) \) denotes the set of labels of the vertices of \( \sigma \) by \( f \), i.e., \( f(\sigma) = \{f(v_0), \ldots, f(v_k)\} \).

\begin{itemize}
  \item \textbf{Lemma 21}. Let \( K \) be a \( n \)-dimensional manifold, let \( U \) be a set of at least \( n + 1 \) elements and let \( f : V(K) \rightarrow U \). If for some subset \( B \subset U \) of size \( n \), there is an odd number of \( B \)-labeled \((n-1)\)-simplexes in the boundary of \( K \), then there is an odd number of \( C \)-labeled \( n \)-simplexes in \( K \), for some set \( C \) of \( n + 1 \) elements, \( B \subset C \subset U \):

\[ ||\{\sigma \in \partial K : \dim(\sigma) = n - 1 \text{ and } f(\sigma) = B\}|| \text{ is odd } \Rightarrow \exists C, |C| = n + 1, ||\{\sigma \in K : \dim(\sigma) = n \text{ and } f(\sigma) = C\}|| \text{ is odd} . \]
\end{itemize}

\subsection{The lower bound argument}

Assume for contradiction that there exists a consistent distributed monitor with \( 2N - 1 \) monitors, for \( \varphi_N \) in \( Lt1_{2k+\epsilon} \) with \( K = N - 2 \). The monitor processes in \( P \) are running a wait-free protocol, communicating with each other by writing and taking snapshots of the shared memory, represented as an array. In any of the executions of this wait-free protocol, eventually each correct monitor \( p_i \) decides a value \( u_i \) (a logical value). We are going to consider two initial assignments of samples to the monitors, \( \tau_n \) and \( \tau_n \) (see end of Section C.1). The corresponding input complex \( \mathcal{I} \) consists of the simplexes \( \tau_n \) and \( \tau_n \), and all their faces. More precisely, we consider simplices of \( \mathcal{I} \) of the following form, where \( \tau_j \) has \( j \) vertices.

Each vertex is a pair, consisting of the id of the monitor and its sample, which is its input to the computation: \( \tau_j = \{(1, (r_1, \ldots, \epsilon)), (2, (r_1 a_1, \ldots, \epsilon)), (3, (r_1 a_1, r_2, \ldots, \epsilon)), \ldots\} \)

We associate with each simplex \( s \in \mathcal{I} \) a value in \{+1, -1\} depending on the value of \( [s] \equiv \varphi_N \) (viewing \( s \) as a trace, by taking its vertices in order of containment). Note that \( \tau_1 \subset \tau_2 \subset \ldots \subset \tau_n \). Also, recalling Observations 16 and 17, we have \( \text{sign}(\tau_i) = (-1)^i \), and every \((\dim(\tau_i) - 1)\)-dimensional face of \( \tau_i \) except \( \tau_{i-1} \) has the same sign as \( \tau_i \).
Theorem 20. Since \( U \) and a id-preserving simplicial map \( c \) from which we conclude that \( \tilde{\sigma} \) simplexes have established above that elements such that the number of \( \psi \)s sign a (not necessarily proper) coloring \( c : V(\mathcal{I}^*) \to U \) on the vertexes of \( \mathcal{I}^* \); For each vertex \( v \) of \( \mathcal{I}^* \), \( c(v) = \text{val}(\delta(v)) \). Given a simplex \( s = \{v_1, \ldots, v_t\} \in \mathcal{I}^* \) we denote (abusing notation) \( c(s) = \{c(v_1), \ldots, c(v_t)\} \subseteq U \) the multiset of colors induced by \( \delta \) of the vertex of \( s \).

**Observation 22.** Let \( \sigma, \sigma' \) be \( j \)-simplexes in \( \mathcal{I} \) with sign(\( \sigma \)) = -sign(\( \sigma' \)) and let \( s, s' \) be \( j \)-simplexes in \( \mathcal{I}^* \). If \( s \in \psi(\sigma) \) and \( s' \in \psi(\sigma') \), \( c(s) \neq c(s') \).

Now we include, for completeness, the argument of [11] to show that for each \( j, 1 \leq j \leq n \), there exists at least one execution of the protocol where the input configuration is \( \sigma_j \) in which the \( j \) participating monitors output \( j \) distinct verdicts. The proof uses Sperner’s lemma and is by induction on \( j \).

Base case \( j = 1 \). By definition, \( \sigma_1 \) is a vertex. By Definition 18(2), \( \psi(\sigma_1) \) is also a vertex \( v \) of \( \mathcal{I}^* \). Since \( \delta \) is a simplicial map, \( \delta(\psi(\sigma_1)) \) is a vertex in \( \mathcal{U} \). Let \( C_0 = \text{val}(\delta(\psi(\sigma_1))) \), i.e., \( C_0 = \{c(v)\} \). That is, \( C_0 \) is the singleton consisting in the verdict output by monitor 1 when it runs alone with input/output pair \((0,1)\).

Induction step. Let \( j \geq 2 \) and assume that the claim is true for \( j - 1 \).

By Definition 18(4), \( \psi(\sigma_j) \) is a \((j-1)\)-psuedomanifold. In order to apply our variant of Sperner’s Lemma, we establish that the number of \((j-2)\)-simplexes in the boundary of \( \psi(\sigma_j) \) that are colored with \( C_{j-1} \) is odd. To that end, let \( s \in \partial \psi(\sigma_j) \) be an \((\text{dim}(\sigma_j) - 1)\) dimensional simplex and assume that \( c(s) = C_{j-1} \). We prove that \( s \in \psi(\sigma_{j-1}) \).

Note that dim(\( s \)) = \( j - 2 \). By Lemma 19(3), there exist a \((j-2)\) dimensional face \( \sigma \) of \( \sigma_j \) such that \( s \in \psi(\sigma) \). Suppose for contradiction that \( \sigma \neq \sigma_j \). It then follows that sign(\( \sigma \)) = sign(\( \sigma_j \)) . By the induction hypothesis, there is a least one \((j-2)\)-simplex \( s' \in \psi(\sigma_{j-1}) \) with \( c(s') = C_{j-1} \). Since sign(\( \sigma \)) = -sign(\( \sigma_{j-1} \)), no \((j-2)\)-simplex in \( \psi(\sigma) \) is \( C_{j-1} \) colored. In particular, \( c(s) \neq C_{j-1} \): a contradiction.

Therefore, the only simplexes \( s \in \partial \psi(\sigma_j) \) that are \( C_{j-1} \) colored are the simplexes \( s \) in \( \psi(\sigma_{j-1}) \) such that \( c(s) = C_{j-1} \). By the induction hypothesis, the number of such simplexes is odd. It thus follows from Lemma 21 that there exists a set \( C = C_j \supseteq C_{j-1} \supseteq U \) of \( j \) elements such that the number of \((j-1)\)-simplexes \( s \in \psi(\sigma_j) \) colored with \( C_j \) is odd.

A similar reasoning can be carried over the collection of simplexes \( \tilde{\sigma}_1 \subseteq \ldots \subseteq \tilde{\sigma}_n \). We have established above that \( \psi(\sigma_n) \) contains at least one \((n-1)\)-dimensional simplex \( s \) with \( c(s) = C_n \), where \( C_n \) is a set of \( n \) verdicts. By applying the same reasoning, considering simplexes \( \tilde{\sigma}_1, \ldots, \tilde{\sigma}_n \) instead, one can show that \( \psi(\sigma_n) \) contains a \((n-1)\)-dimensional simplex \( \tilde{s} \) colored with a set \( \tilde{C}_n \subseteq U \) of size \( n \). Since sign(\( \tilde{\sigma}_n \)) = \((-1)^{n+1} = -\text{sign}(\sigma_n), \tilde{C}_n \neq C_n \), from which we conclude that \(|U| \geq n + 1\).
